

Computer Graphics Comprehensive Exam

2007-2008

NAME:

Note: This exam is *closed-book*.

The exam consists of 5 questions. Each question is worth 20 points. Please answer all the questions in the space provided, overflowing on to the back of the page if necessary.

This exam has been designed to take 1 hr.

1. [20 points] General.

1A [5 points]. What is the relationship between the RGB and CMY color spaces?
How are colors in one space computed from colors in the other space?

1B [5 points]. What is a z-buffer and how is it used in computer graphics?

1C [5 points]. What is quantization? And why can it be used for compression?

1D [5 points]. Aliasing is an undesirable artifact of generating images using computers. What causes aliasing?

[20 points] Shading Polygon Meshes

Polygon meshes are the most common representation of geometric shapes in computer graphics. Many computer graphics algorithms operate on polygon meshes. For this question, assume that the mesh is made of polygons with any number of sides.

2A [5 points]. What is the difference between Gouraud shading and Phong shading?

All shading algorithms require a surface normal. In the case of Phong and Gouraud shading, a surface normal is required for each vertex in the mesh. Assume that you are given a polygon mesh without normals. That is, with just a position for each vertex.

2B [15 points]. Describe a method for computing the normal at each vertex. Your explanation should explain the math of how to compute the normal from the vertex positions (7.5 points) and how to define a polygon mesh data structure that makes this computation efficient ($O(n)$ where n is the number of vertices in the mesh).

3. [20 points] Bezier Curves.

One the most important primitives in computer graphics is the cubic Bezier Curve. The cubic Bezier curve is constructed from a control polygon consisting of 4 points as shown below.

The curve is given by the parametric equation $P(t)$ where t lies between 0 and 1. This diagram illustrates two key properties of Bezier curves. First, the curve passes through the end points P_0 and P_3 . That is, $P(0)=P_0$ and $P(1) = P_3$. Second, the curve is tangent to the control polygon at the end points. Precisely, $T(0)=3(P_1-P_0)$ and $T(1)=3(P_3-P_2)$. $P(t)$ can be evaluated using a recursive algorithm. Recall the classic result that $P(1/2) = 1/8 P_0 + 3/8 P_1 + 3/8 P_2 + 1/8 P_3$.

One reason Bezier curves are so popular is that they can be used to accurately approximate other curves. Suppose you want to approximate the circular arc shown below. Where would you position the control points P_0, P_1, P_2, P_3 to approximate this arc with a bezier curve whose $P(1/2)$ is the arc's midpoint ($\cos 45, \sin 45$)? Provide the coordinates of the positions of these points.

4. [20 points] Shading

There are two important shading models used to model the appearance of real materials, the diffuse and specular (sometimes called glossy) models. In this problem, just consider point light sources.

4A [10 points]. What is the equation for diffuse reflection? That is, what is the reflected color given the direction to the eye \mathbf{E} , the surface normal \mathbf{N} , and the direction of the point light source \mathbf{L} . Include other parameters that might be useful. Explain briefly the physics underlying diffuse reflection. Finally, give an example of a material whose appearance can be modeled using diffuse reflection.

4B [10 points]. Give an equation for specular or glossy reflection. Explain briefly the physics underlying this type of reflection. Give an example of a material that can be modeled using specular reflection.

5 [20 points] Matrices and the Matrix Stack

5A [5 points]. Transformations in computer graphics are represented with 4x4 matrices even though the world is three-dimensional. Why are 4x4 matrices used instead of 3x3 matrices?

In a typical graphics system, a current transformation matrix T is part of the graphics state. Each time a triangle or line is drawn, this matrix transforms the vertices. Assume that the vertex position p is given by a column vector. With this assumption, the transformation involves a matrix-vector product, $T * p$.

5B [5 points]. In a graphics program, commands exist to modify the current transformation. For example, `translate(x,y,z)` and `rotatex(30)`. What happens in the graphics system when a transformation command is given? Be precise.

5C [5 points]. The order of the transformations sometimes matters. That is, a program that first executes `translate(x,y,z)` and then executes `rotatex(30)` may lead to a result different than one that first executes `rotatex(30)` and then `translate(x,y,z)`. Why does the order matter? If order does not always matter, can you give an example when it does not matter?"

5D [5 points]. Commands also exist to push and pop the current transformation onto a stack. Why is it useful to be able push and pop the current transformation?
